Online Survey of Digital Reading by Adults with Low Vision

Yueh-Hsun Wu, MS,1* Christina Granquist, BS,1 Rachel Gage, BA,1 Michael D. Crossland, PhD, MCOptom,2 and Gordon E. Legge, PhD1

SIGNIFICANCE: Access to digital text is increasingly widespread, but its impact on low-vision reading is not well understood.

PURPOSE: We conducted an online survey of people with low vision to determine what assistive technologies they use for visual reading, their preferred text characteristics, and the time they devote to reading digital and hard-copy text.

METHODS: One hundred thirty-three low-vision participants completed an online survey. Participants reported the nature and history of their low vision, their usage of different assistive technologies, and time devoted to five visual reading activities.

RESULTS: The three largest diagnostic categories were albinism (n = 36), retinitis pigmentosa (n = 20), and glaucoma (n = 15). Mean self-reported acuity was 0.93 logMAR (range, 0.1 to 1.6 logMAR). Mean age was 46 years (range, 18 to 98 years). Participants reported on percentage time spent reading using vision, audio, or touch (braille). Seventy-five percent of our participants did more than 50% of their reading visually. Across five categories of reading activities—work or education, news, pleasure, spot reading, and social networking—participants reported more time spent on digital reading than hard-copy reading. Eighty-nine percent of our participants used at least one technology from each of our two major categories of assistive technologies (digital content magnifiers and hard-copy content magnifiers) for visual reading.

CONCLUSIONS: Despite the growing availability of digital text in audio or braille formats, our findings from an online sample of people with low vision indicate the continuing importance of visual reading. Our participants continue to use technology to access both hard-copy and digital text, but more time is devoted to digital reading. Our findings highlight the need for continued research and development of technology to enhance visual reading accessibility.

Supplemental Digital Content: Direct URL links are provided within the text.

By a recent estimate, there are 5.7 million people in the United states with acuity poorer than 20/40.1 For many of them, the primary consequence of their low vision is difficulty reading.2

The advent of digital media and the ever-expanding variety of digital reading devices on the market have changed people’s reading habits. People now can easily access digital materials, such as web pages, e-books, and online user manuals. Hence, digital reading has become a major activity in modern society. A 2010 survey3 revealed that 83% of normally sighted participants spent more time on digital reading than before. However, more than 90% of participants in the same study preferred hard-copy material to digital material for reading.2 Although these percentages may have changed, it seems clear that normally sighted readers make use of both digital and hardcopy text.

Current digital devices offer low-vision readers flexibility in customizing the layout and appearance of text. Magnification can be achieved by zooming functions on smartphones and tablets. Laptops and desktop computers with bigger displays can present larger print sizes and in turn can enable a low-vision user to achieve a higher level of magnification. These useful features make digital media more accessible to people with low vision. An online survey of visually impaired people conducted in the United Kingdom found that more than three-quarters of participants (81%) had a smartphone, and almost half of them used tablets.4 Another study showed that normally sighted and visually impaired people were equally likely to own a handheld video device, such as an iPad or a PlayStation Portable.5

Some laboratory studies have demonstrated the benefit of using these digital devices for reading. For instance, people with AMD can read faster on an iPad than on hard-copy paper or an e-book reader, when given the same print size across all media, but hard-copy paper was still considered easier to use.6 In another study testing reading ability with the iPad in a large group of people with low vision, 87% were able to read a digital news article comfortably by zooming in and changing the contrast polarity.7 Morrice et al.8 found that only experienced low-vision iPad readers can read as fast as low-vision closed-circuit television readers, but average reading speed was not significantly different between an iPad and closed-circuit television for nonexperienced readers. Helpful built-in features, such as zoom and contrast polarity, can possibly make mainstream digital devices accessible to visually impaired users.9

People with low vision are no longer limited to the use of optical magnifiers but instead have a variety of choices to help them read in their daily lives. Fok et al.10 showed that many digital devices and technologies, such as screen magnification software, large monitors, and screen reader software, serve as important and useful assistive technologies for people with low vision. Another online survey conducted by an online community, Web Accessibility In Mind (WebAIM), also reported that people with low vision make use of different assistive features, such as screen readers, zooming, and contrast polarity options, to access web content.11

We have reported detailed results from one section of the survey in a separate publication.12 This part of the survey asked participants...
to view a sample text passage on their primary reading display and report on the viewing distance, screen size, number of lines visible, and number of characters per line. Our goal in obtaining this information was to determine how people with low vision arrange their viewing configuration to achieve adequate magnification. In brief, most of the low-vision participants from our sample achieved their desirable magnification by a combination of two factors: reduced viewing distance compared with normally sighted controls and increased on-screen letter size. A majority (72%) of those who completed this part of the survey relied more on increased on-screen letter size.

The primary aim of our online survey was to understand the reading behavior of people with low vision in the digital era. This report describes findings from our survey concerning what devices people with low vision use for visual reading, their preferred display settings, how much time they spend on different reading activities, and how their acuity affects their choice of device or the amount of time they spend on reading.

METHODS

Participants

The research protocol was approved by the University of Minnesota institutional review board and followed the tenets of the Declaration of Helsinki. Online consent was provided by each participant before proceeding to the survey. One hundred thirty-three participants were recruited by word of mouth and through several visual impairment-related organizations in the United States, such as the American Council of the Blind and Foundation Fighting Blindness. One hundred twenty-six of our participants were from 33 U.S. states, two from Canada, one from Taiwan, one from Uruguay, and three undesignated. The three most cited states were Minnesota (n = 31), California (n = 9), and Pennsylvania (n = 9). Screening questions ensured that participants were 18 years or older, read visually in their daily lives for some purposes, and had low vision with no major changes to their vision within the past year. For purposes of this survey, low vision was defined as an acuity of less than 20/60 with best-corrected glasses in the better eye or a visual field less than 20°.

Materials

Participants completed the online survey on their own time and with their own devices between January 2017 and March 2018. The online survey was designed to be accessible by screen-magnification and screen-reading software. The questions used in the survey can be found in the Appendix (available at http://links.lww.com/OPX/A444).

The survey consisted of five sections:

1. Demographics: Questions about age, education level, and employment status
2. Nature and history of low vision: Questions about the participant’s cause of low vision, visual acuity, type of visual field loss if any, and percentage of time spent on visual, audio, and braille reading
3. Usage of assistive devices/technologies: Participants reported the devices they used for visual reading. Two categories of assistive technologies were included in this section: digital content magnifiers and hard-copy magnifiers. Digital content magnifiers refer to hardware or software that magnifies text within digital materials, such as online web pages, online news, e-books, or scanned materials. This category includes smartphones, tablets, e-book readers, laptops, desktop computers, and screen magnification software installed on laptops or desktops. Hard-copy magnifiers include devices that are designed for reading hard-copy materials, such as printed books, newspapers, medicine labels, and food packaging. This category includes optical magnifiers (handheld, stand, and mounted on glasses), closed-circuit televisions, and portable handheld electronic magnifiers. Magnification apps on mobile devices were included in this category because these apps use the built-in camera to magnify hard-copy text.
4. Assessment of magnification: The participant viewed a paragraph of text from Alice in Wonderland on their chosen reading display and reported properties of viewing configuration, including the viewing distance, dimensions of the display, and the number of characters on a line. These data were used to estimate the roles of viewing-distance magnification and letter-size magnification in relation to the participant’s acuity. Detailed findings from this section of the survey were reported in Granquist et al.12 and will not be further described here.
5. Reading habits: Participants rated how much time they spent on several categories of reading in digital or hard-copy format in the past year, using a 5-point scale: 1, rarely or never; 2, occasionally, once a week or less; 3, frequently, at least a few days per week; 4, almost every day, at least once; and 5, daily heavy use. Five different activities were (1) work or educational reading; (2) news reading; (3) pleasure reading of books or articles; (4) spot reading, such as recipes, food labels, restaurant menus, phone numbers, and TV listings; and (5) social networking, such as e-mail communication and social media. For all except social networking, participants provided separate ratings for hard-copy and digital reading. Participants who learned to read before the onset of low vision were also asked to provide ratings for their reading habits while they had normal vision, but these data on reading with normal vision are not included in this report.

RESULTS

Characteristics of the Participant Sample

The mean age of our 133 participants was 46.03 years (SD, 17.42 years; median, 48 years; range, 18 to 98 years). Most of the participants reported acuity as Snellen ratios. We converted these values to corresponding logMAR values for purposes of calculation. The average self-reported binocular acuity was 0.93 logMAR (SD, 0.35 logMAR; range, 0.1 to 1.6 logMAR) from a subgroup of 106 participants providing numerical acuities. Fifty-four percent of our participants reported that they experienced nystagmus. The group with nystagmus had a significantly worse average acuity (0.99 [SD, 0.31 logMAR] than those without nystagmus (0.85 [SD, 0.39] logMAR; f_{(9)}^{2} = 2.01; P < .05). We did not find important differences in our other measures between the participants with and without nystagmus. Forty-six percent of participants reported that they had peripheral-field vision loss, 14% had central field loss, and 38% had no visual field loss. Nine percent of our participants reported that they had hearing loss.
Participants were asked to report the cause(s) of their low vision. The three most common causes were albinism (36), retinitis pigmentosa (20), and glaucoma (15). Twelve participants listed multiple causes of their low vision. Table 1 lists the self-reported diagnoses.

Seventy-five percent of the participants identified as female, and 78% of them had a college/university degree or higher. Forty-nine percent of them were employed, 30% were unemployed, and 21% were retired. Sixty-three percent had low vision since birth, 14% developed low vision before 18 years old, and 20% had late-onset low vision after age of 18 years. The late-onset group had better average acuity (mean, 0.63 [SD, 0.36] logMAR) and was older (mean, 61.8 [SD, 12.92] years) than the rest of the sample.

To assess the reliability of self-reported acuities, we assembled data for 20 participants for whom we had both self-reported acuities and laboratory-measured acuities. Fig. 1 shows a scatterplot of the data for 20 participants for whom we had both self-reported acuities and laboratory-measured acuities. The correlation between the two measures was 0.93 (and the mean absolute difference was 0.13 (SD, 0.11) logMAR. Of the values. The mean difference was 0.03 (SD, 0.18) logMAR, with a greater probability of 75% or more visual reading. Thirty-seven participants in the vision primary group had an acuity better than 1.0 logMAR, and five had an acuity worse than 1.0 logMAR.

In section 5 of the survey, we were interested in both the overall amount of visual reading and the differences between hard-copy and digital reading. For four of the five activities, more than half of our participants reported that they used digital reading on a daily basis (rating 4 or 5)—work/educational reading (65%), news reading (50%), spot reading (59%), and social networking (77%). Fewer (44%) reported using digital reading for pleasure on a daily basis (rating 4 or 5). Clearly, this group of low-vision participants engage in extensive daily use of digital reading. Fig. 3 shows the proportion of ratings on each activity.

Wilcoxon signed rank tests showed that our participants spent significantly more time on digital reading than hard-copy reading across all four reading activities—work/educational reading (Z = −5.44; P < .001; effect size [r], 0.47), news reading (Z = 6.5; P < .001; effect size [r], 0.57), pleasure reading (Z = −4.44; P < .001; effect size [r], 0.38), and spot reading (Z = −5.16; P < .001; effect size [r], 0.45).

### Reading Habits

In section 2 of the survey, we asked our participants how they distributed their daily reading between visual, auditory, and braille sources. Fig. 2 plots the proportion of visual reading as a function of acuity. A χ² goodness-of-fit test revealed that the number of participants who spent more than 50% on visual reading (n = 101) was significantly greater than the number who spent more than 50% of time on auditory reading (n = 31) or Braille reading (n = 1) (χ² = 118.8, P < .001). The effect size (Cohen W) was 0.95. Forty-four percent of our participants did more than 75% of their reading visually (vision primary subgroup), and only 11% did less than 25% of their reading visually (nonvisual subgroup). The vision primary subgroup had a better average acuity (mean, 0.82 [SD, 0.3] logMAR) than the nonvisual subgroup (mean, 1.18 [SD, 0.31] logMAR; W = 3.18; P < .01, with Cohen effect size (d) value of 1.18.

### Assistive Devices

In section 3 of our survey, participants reported the devices they used for visual reading (Table 2). The devices can be categorized into two groups: digital content magnifiers and hard-copy magnifiers. Most of our participants (98%) used two or more devices for visual reading. Ninety-four percent of them reported using at least one type of digital content magnifier, and 95% used at least one hard-copy magnifier. Eighty-nine percent of our participants used devices from both categories. The three most frequently reported devices all came from the digital content magnifier category: smartphones (69%), screen magnification software (62%), and

tablets (59%). The two least used devices were in the hard-copy magnifier category: stand magnifiers (10%) and magnifiers mounted on glasses (16%). Additional analysis revealed that 87% of our participants used either laptop or desktop computers for visual reading. For this group of laptop and desktop users, 68% of them used magnification software on their computers. Eighty percent of our participants used either a smartphone or tablet, and 44% of these smartphone or tablet users used magnification apps.

We used logistic regression to explore the use of acuity, education, and age in predicting device usage. The only significant relationship occurred for acuity and whether a participant used a closed-circuit television (see Appendix Table A2, available at http://links.lww.com/OPX/A445). The coefficient of the logistic model was statistically significant (coefficient, 2.45; \( P < .001 \)).

Preferred Text Characteristics

We asked our participants about their preferences for contrast polarity and font. Thirty-nine percent reported that they preferred black text on a white background. A larger group of participants (46%) preferred reversed contrast (white text on a black background), and 14% of participants had no preference for contrast setting. On average, the group that preferred reversed contrast had significantly worse acuity (1.03 [SD, 0.35] logMAR) than the group who preferred black-on-white (0.82 [SD, 0.33] logMAR) (\( t_{85.86} = 2.86, P < .01 \)). For the three largest diagnostic categories in our survey (Table 1), the numbers of participants preferring standard contrast (black-on-white) and reversed contrast (white-on-black) were as follows: albinism, 16 and 15; retinitis pigmentosa, 5 and 13; and glaucoma, 3 and 8, respectively. Although there were only six participants with AMD in our group, five of them preferred black-on-white contrast.

We also asked our participants to report their preferred font type, if any. Only 51 participants expressed a preference for one or more fonts. The most frequent fonts reported were Arial (n = 37), Times New Roman (n = 16), and Verdana (n = 7) (Table 3).

DISCUSSION

Our goal in the current study was to learn about visual-reading activities by people with low vision and the devices they use. Given the growing availability of text in audio formats and technology for text-to-speech and text-to-braille, we wondered if our participants might show diminished reliance on visual reading as a whole. To the contrary, four of our findings indicate the continuing importance of visual reading to low-vision individuals. First, for all five categories of digital reading activities in our survey, our participants reported...
substantial visual reading. For four of the five categories (except pleasure reading), they read daily.

Second, there was a high rate of adoption of multiple visual-reading devices (by more than 90% of our participants), and 89% had at least one aid from our two main categories (digital-content devices and hard-copy reading devices). Third, vision was the primary reading modality for most of our participants, even for many with moderate to severe acuity loss. Presumably, those with low acuity who continue to read visually make use of high magnification.

Fourth, we found that our participants spent significantly more time reading digital text than hard-copy text across the different activities listed in our survey. This result is similar to the trend found in the normally sighted population. The growing range of digital materials enhances text accessibility for visually impaired people. The expansion of built-in features, such as screen magnification, the ability to adjust print size, and contrast polarity, makes digital reading more accessible than hard-copy reading.

These findings reinforce our view of the importance of continued research on low-vision reading in the digital era and ongoing efforts to enhance the visual accessibility of text.

Devices and Technologies Used

Our findings on everyday reading activities indicated that more time was devoted to digital reading than hard-copy reading. The overall most used devices (Table 2) were from the digital content magnifier category: smartphones (used by 69% of our participants), screen magnification software (62%), and tablets (59%). By comparison, the two least used devices were from the hard-copy magnifier category: stand magnifiers (10%) and magnifiers mounted on glasses (16%).

Despite a smaller screen size, smartphones were the reading devices used most frequently by our participants. The popularity of these devices, along with smartphones and tablets, among both normally sighted and visually impaired individuals may indicate that the features of accessibility built in those devices facilitate their use for reading despite their small displays. Crossland et al. found an even higher adoption of smartphones in a survey of visually impaired users (81%), but their survey focused on general use and not specifically on visual reading. For our participants, it is likely that smartphones were used for spot reading tasks and not for continuous reading. In support of this conjecture, in the portion of our survey described by Granquist et al., we asked our participants to report on the device used for reading a sample passage from Alice in Wonderland. For the 75 participants who completed this portion of the survey, 60 used a desktop or laptop computer, 10, a tablet; two, a closed-circuit television; and only three used a smartphone. Moreover, Crossland et al. found that most of their visually impaired participants used smartphones for text messaging (90%) and Internet browsing (80%), which are spot reading tasks.

Despite the shift to digital reading, our participants continue to read hard copy materials. Ninety-five percent of our participants reported using at least one type of hard-copy magnifier for visual reading. In addition, almost half of our participants reported using closed-circuit televisions, which are designed for reading hard-copy materials. Our analysis showed that participants with worse acuities were more likely to use a closed-circuit television for visual reading.

Preferred Text Characteristics

Our participants included a surprisingly large number (46%) who preferred reversed-contrast text (white letters on a black background) compared with 39% who preferred standard black-on-white text. It has long been known that some people with low vision read better with reversed-contrast text. Legge reviewed research indicating that participants with cloudy ocular media (from cataract, corneal damage, or vitreous debris) sometimes have better reading performance with reversed contrast. In the current study, nine of 15 participants with cataract or other disorders with cloudy ocular media reported a preference for reversed contrast. Many in our largest categories—albinism, retinitis pigmentosa, and glaucoma—also reported a preference for white-on-black text. The preference

</table>
of reversed contrast could be the result of photophobia, which is a common symptom shared by people with albinism\textsuperscript{17} and retinitis pigmentosa.\textsuperscript{15} Ehrlich\textsuperscript{19} has reported that 21 of 23 patients with severe retinitis pigmentosa read better with reversed-contrast text. We note that our participants who preferred reversed contrast had overall poorer acuity than the remaining participants. We also note that five of our six AMD participants preferred regular black-on-white text. Further study would be required to determine if preferences correlate highly with measurable properties of reading performance such as reading speed or critical print size.

Although only 51 participants expressed font preferences, the Arial font family was the most cited font style (Table 3). This finding coincides with the guideline for large-print documents recommended by the American Council of the Blind,\textsuperscript{20} which suggests using Sans Serif fonts such as Arial. Only three of our participants mentioned the APHont font, which was designed for low vision by the American Printing House for the Blind.\textsuperscript{21} None of our participants mentioned Tiresias, a font designed by the Royal National Institute of Blind People in London. Previous studies have been unable to demonstrate a consistent benefit of specially designed fonts for low vision or for specific mainstream fonts.\textsuperscript{5,22,23} There is some evidence, however, that fonts with increased between-letter spacing, such as courier, can be helpful.\textsuperscript{23–25}

**Study Limitations**

We address three significant limitations of our study. First, we acknowledge that our low-vision sample is not representative of the low-vision population as a whole. In contrast to patients visiting low-vision clinics, many of whom are older and have macular degeneration,\textsuperscript{26} a majority of our participants had early-onset low vision, more had peripheral-field loss than central-field loss, and most of them had a college degree or higher. Our online survey targeted a group of people who are familiar and comfortable with computer technology and who make regular use of digital reading in their daily lives, and as such, the current study provides information about visual reading among a technologically savvy group of people with low vision. The characteristics of our sample were similar to the sample composition of other online survey studies aiming for understanding the technology usage among people with low vision.\textsuperscript{4,11} One advantage of an online survey over a clinic-based survey is the possibility of reaching people who do not have easy geographical access to a low-vision clinic. It is certainly possible that access to low-vision aids and also access to digital content might depend on rural versus urban residency or other geographical variables. Our study shares with most clinical studies the difficulty in recruiting a truly representative sample of low-vision participants.

Second, in some cases, we have related our findings to the visual acuities of our participants. In so doing, we have relied on self-reports rather than direct clinical data, an inherent limitation of a survey study. It is known that self-reported subjective ratings of vision status are influenced by nonvisual factors such as race and socioeconomic status.\textsuperscript{27–29} These studies asked participants to rate the quality of their vision on a numerical scale (1 to 10) or using descriptors such as excellent, fair, and poor. We did not ask our participants to make subjective ratings of their vision but to report acuity scores, presumably obtained from their eye doctors. Our sample of low-vision participants tended to be fairly young and well educated. Most (81\%) reported an eye examination within the past year, and our eligibility criteria included stable vision over the past year. Furthermore, we encouraged our participants to check their clinical records or check with their eye doctor to acquire their visual acuity if they did not know it. These are factors that contribute to reliable self-reporting of eye conditions. Compared with the findings of Kiser et al.\textsuperscript{30} on repeat reliability, which reported that the criterion for a significant change in low-vision acuity should be two to three lines (0.2 to 0.3 logMAR), our data shown in Fig. 1 from a sample of 20 low-vision participants from whom we have both self-reported and laboratory measurements showed a mean absolute difference of only 0.13 logMAR. Nevertheless, we acknowledge that the self-reported clinical information is likely to be noisier than corresponding clinical or laboratory data. The 95\% limit of agreement in our 20-participant data was 0.35 logMAR, which is larger than the range of 0.2 to 0.3 logMAR found in the study of Kiser et al.\textsuperscript{30} Factors contributing to inaccuracy in reported acuity would include changes since the last clinic visit, inaccuracies in the clinical measurements themselves, and faulty memory. In addition, we converted visual acuities, reported as Snellen ratios, into logMAR units for the purpose of calculation and for the journal’s international readership. It is likely that the acuities reported by our participants may have often been measured with Snellen charts rather than logMAR charts, contributing noise to our data.

Finally, given the rapid progress in digital distribution of information and the continuing development of assistive technology, we recognize that our findings provide only a fleeting snapshot of the ecology of low-vision reading. It will be valuable to compare our results with similar data in future years.

Despite these limitations, our study sheds light on the reading behavior of an online group of people with low vision in the current digital era. Given the increasing number of low-vision individuals and the popularity of digital content, our findings reinforce our view of the importance of continued research on low-vision reading and ongoing efforts to enhance the visual accessibility of text at the design stage.
